(Received 22 August 2008; accepted 11 October 2008; published online 7 November 2008)

We observed sizable eigenfrequency shifts in spin-polarized dc-current-driven vortex gyrotrropic motions in a soft magnetic nanodot, and clarified the underlying physics through micromagnetic numerical calculations. It was found that the vortex eigenfrequency is changed to higher (lower) values with increasing Oersted field (OH) strength associated with the out-of-plane dc current for the vortex chirality parallel (antiparallel) to the rotation sense of the OH circumferential in-plane orientation. The eigenfrequency shift was found to be linearly proportional to the current density \( j_0 \) in the linear regime as in \( \Delta \nu_D = \pm \eta j_0 |G| \), where \( G \) is the gyrovortex constant and \( \eta \) is a positive constant, e.g., \( 1.9 \times 10^{-8} \text{ erg/A} \) for a model Permalloy dot of 300 nm diameter and 20 nm thickness. This behavior originates from the sizable contribution of the OH to the effective potential energy of a displaced vortex core in the gyrotrropic motion. The present results reveal that \( \nu_D \), an intrinsic dynamic characteristic of a given nanodot vortex state, is controllable by changes in both the density and direction of spin-polarized out-of-plane dc currents. © 2008 American Institute of Physics. [DOI: 10.1063/1.3012380]

Recent studies\(^{1–6} \) have established that the spin-transfer torque (STT) of spin-polarized electric currents is a promisingly reliable means of switching the orientation of magnetizations (M) in magnetic particles of submicron size or less. The STT thereby has been practically used in information storage,\(^{1,2} \) devices, due to several advantages including low-power, ultrafast, and reliable information recording, and in frequency-tunable microwave oscillators.\(^{4,7,8} \) Moreover, the STT effect on magnetic vortex excitations in nanodot and nanopillar systems has begun to receive a great deal of attention owing to its potential applications to future information storage and microwave oscillator devices.\(^{9–20} \) For instance, the current-driven vortex gyrotrropic oscillation\(^{9–13} \) and vortex core (VC) M switching\(^{12–20} \) in confined magnetic systems have been observed both experimentally\(^{9–11,13,14} \) and numerically.\(^{15–20} \) Despite the several studies conducted on the STT effect on such vortex excitations, quantitative understanding of the Oersted field (OH) effect of the spin-polarized currents has been lacking, even though this type of field has been reported to make sizable contributions to M reversals\(^{5,21,22} \) and VC oscillations.\(^{9,10,13} \)

In this letter, we report the observation of sizable shifts in the intrinsic eigenfrequency \( \nu_D = (1/2 \pi) \omega_D \) of vortex gyrotrropic motions in a laterally confined thin-film nanodot. The physical origin of this behavior was qualitatively understood by considering the Zeeman contribution of the spin-polarized-current-induced circumferential OH to the effective potential energy of a displaced VC. We found an analytical equation that relates the eigenfrequency shift to the current density and its flowing direction. The present work provides a reliable means of manipulating \( \nu_D \) of a given vortex state by using spin-polarized out-of-plane dc currents, which manipulation that might be applicable to frequency-tunable oscillators in the subgigahertz range without additionally applied magnetic fields.

To conduct micromagnetic numerical calculations of vortex dynamics associated with a low-frequency translation mode (the so-called gyrotrropic motion) in a nanodot, we used the LLG code,\(^{23} \) which utilizes the Landau–Lifshitz–Gilbert equation of motion, which includes the STT term,\(^{1,2} \) expressed as \( \mathbf{T}_{\text{STT}} = (a_{\text{STT}} / M_s) \mathbf{M} \times (\mathbf{M} \times \mathbf{n_p}) \), with \( a_{\text{STT}} = (1/2 \pi) h \gamma P j_0 / (\mu_0 2 e M_s L) \). \( \mathbf{n_p} \) is the unit vector of the spin polarization orientation, \( h \) is the Planck constant, \( \gamma \) is the gyromagnetic ratio, \( P \) is the degree of spin polarization, \( j_0 \) is the current density, \( \mu_0 \) is the vacuum permeability, \( e \) is the electron charge, \( M_s \) is the constant magnitude of \( \mathbf{M} \), and \( L \) is the thickness of a free magnetic layer. We employed, as a model, a circular-shaped Permalloy (Py) (Ni\(_{80}\)Fe\(_{20}\)) nanodot of \( 2R = 300 \text{ nm} \) and \( L = 20 \text{ nm} \) [see Fig. 1(a)]. An equilibrium vortex state in the given dot can be characterized by the vortex integers of the chirality \( c \) and the polarization \( p \): \( c = +1 \) (−1) corresponds to the counterclockwise (CCW) [clockwise (CW)] rotation sense of the in-plane curling \( \mathbf{M} \), and \( p = +1 \) (−1) corresponds to the upward (downward) \( \mathbf{M} \)

FIG. 1. (Color online) (a) Vortex state with upward \( \mathbf{M} \) orientation of its VC and CCW in-plane curling \( \mathbf{M} \) in circular Py dot of indicated dimensions. The color and height display the local in-plane \( \mathbf{M} \) and out-of-plane \( \mathbf{M} \) components, respectively. (b) OH strength profile along radial distance \( |r| \) for indicated different \( j_0 \) values.
orientation of the VC. For example, the vortex state of \( c = +1 \) and \( p = +1 \) is illustrated in Fig. 1(a). In the present simulations, we used \( p = +1 \) and \( \mathbf{m}_p \) was in the \(-z\) direction [antiparallel (AP) to the vortex polarization]. Spin-polarized currents were applied for 100 ns through the dot of the vortex state toward the \(+z\) direction. Then, we investigated vortex gyrotropic motions in the linear regime.

In order to examine how the OH effect of out-of-plane dc currents is considerable in vortex gyrotropic motions, first we calculated the strength profile of the OH produced for different \( j_0 \) values based on Biot–Savart’s formulation \( \mathbf{H}_0 (\mathbf{r}) = (1/2) j_0 \mathbf{i}_p (\mathbf{z} \times \mathbf{r}) \), where \( \mathbf{r} \) is the radial vector from the center position (\( \mathbf{r} = 0 \)) and \( \mathbf{i}_p \) is the direction of the applied currents, i.e., \( \mathbf{i}_p = +1 (1) \) corresponds to the \(+z (−z)\) direction. The CCW and CW rotation senses of the circumferential OHs are thus determined simply by the sign of \( \mathbf{i}_p \), i.e., corresponding to \( \mathbf{i}_p = +1 \) and \(-1\), respectively. For \( \mathbf{i}_p = \pm 1 \), the OH strength profile versus \( |\mathbf{r}| \) for different \( j_0 \) values are shown in Fig. 1(b). At the center of the dot, \(|\mathbf{H}_0 (0)| = 0 \) for all of the \( j_0 \) values, but sufficiently large values of \( \sim 100 \) Oe are obtained at the edge, which values can modify vortex gyrotropic motions.

Figure 2 displays the orbital trajectories of the spiral motions of a VC in the linear regime driven by a spin-polarized current with \( j_0 = 1.3 \times 10^7 \) A/cm\(^2\) for the three different indicated cases: only the STT effect in the absence of the OH and the STT effect considering the OH with its circumferential in-plane orientation parallel (P) and AP to a given vortex chirality (\( c = +1 \) or \(-1\)). These three different cases hereafter are abbreviated as case I, “STT only;” case II, “STT+OH(P);” and case III, “STT+OH(AP).” For all of the cases, the observed orbital trajectories show spirally rotating motions with \textit{exponentially increasing} orbital radii. In cases of in-plane oscillating currents \(^{11,14,16,18}\) or fields, \(^{16,17,24}\) the increasing orbital radius converges exponentially to a certain steady-state orbital radius. \(^{16,17,24}\) In contrast, the out-of-plane spin-polarized current-driven vortex gyrotropic motions show exponentially increasing orbital radii with distinctive rates for the different cases of I, II, and III. Such an exponentially increasing orbital radius \(^{26}\) is one of the characteristic dynamic properties of spin-polarized out-of-plane current-driven vortex gyrotropic motions.

From fast Fourier transforms (FFTs) of the time variation of the \( x \)-component of the VC position, we obtained FFT spectra as a function of the frequency. As revealed in the inset of Fig. 3, the eigenfrequencies and their full widths at half maximum (FWHMs) in cases I, II, and III are very contrasting. The value of \( \nu_0 = 580 \) MHz (FWHM: 30 MHz) in case I was shifted to a higher value, 645 MHz (FWHM: 50 MHz) in case II, and to a lower value of 515 MHz (FWHM: 40 MHz) in case III. In order to quantitatively clarify the observed OH effect on the eigenfrequency shifts, we plotted the modified eigenfrequency (\( 1/2 \pi \omega_0 \)) as a function of \( j_0 \) for those \( j_0 \) values larger than a critical current density \( j_{\text{cri}} \). Here \( j_{\text{cri}} \) is defined as a threshold current density above which the vortex gyrotropic motions can be excited with a continuously increasing orbital radius. \(^{27}\) It is clearly shown that \( (1/2 \pi) \omega_0 \) increases (decreases) linearly with increasing \( j_0 \) strength for the P (AP) orientation between \( c \) and the rotation sense of OH (Fig. 3). From the linear fits (lines) to the simulation results (symbols), we could find a relationship between \( (1/2 \pi) \omega_0 \) and \( j_0 \). Note that \( (1/2 \pi) \omega_0 \) does not depend on \( j_0 \) for STT only (case I), and that for cases II and III, the values of \( (1/2 \pi) \omega_0 \) converge to \( (1/2 \pi) \omega_0 = 580 \) MHz, with the approach to \( j_0 = 0 \), according to the slope \((1/2 \pi) \omega_0 \) of \( j_0 = 580 \) MHz. The sign of \( (1/2 \pi) \omega_0 \) is determined by the sign of the product of \( c \) and \( i_p \), i.e., \( c i_p = +1 \) \((-1)\) corresponding to the P (AP) orientation between the vortex chirality and the rotation sense of OH.

Next, in order to elucidate the underlying physics of the OH effect on the modification of the \( \omega_0 \) value and to obtain a quantitative relation between \( \omega_0 \) and \( j_0 \), we used the known relation \( \omega_0 = \omega_0 = \kappa_0 / |G| \) for a small Gilbert damping parameter, e.g., here \( \alpha = 0.1 \) \(^{17,24}\) where \( G \) is the gyromagnetic constant and \( \kappa_0 \) is the intrinsic stiffness coefficient of the potential energy. \(^{28}\) For a given dot, \( G \) and \( \kappa_0 \) are constant, 6.14 \times 10^{-10} \) erg s/cm\(^2\) and 2.3 erg cm\(^2\), respectively, for the model used in this study. Thus \((1/2 \pi) \omega_0 = 596 \) MHz, a value close to that (580 MHz) obtained from the simulation result. Therefore, the modified \( \omega_0 \) values can be evaluated directly from the modified \( \kappa \) values due to the OH contribution. For a small displaced VC, the potential energy is given as \( W(X) = W(0) + \kappa_0 X^2 / 2 \), considering both the exchange and magnetostatic energies. To obtain the relation of the OH contribution to \( \kappa \), the \( \kappa \) value can be determined from the plot of \( W_{\text{tot}}(X) \) versus \( |X|^2 \) (see the left top panel of Fig. 4), where the \( W_{\text{tot}}(X) \) were obtained from the simulation results for cases I, II, and III. As seen in the right top panel of Fig. 4, it is evident that the Zeeman energy term modifies the slope of the \( W_{\text{tot}} \) versus \( |X|^2 \) value in each case, in contrast, the magnetostatic and exchange energy contributions to the modification of the \( W_{\text{tot}}(X) \) versus \( |X|^2 \) in cases I, II, and III are negligible.

The linear fits to the \( W_{\text{tot}} \) versus \( |X|^2 \) for the different \( j_0 \) values allow us to numerically estimate the \( \kappa \) values according to \( j_0 \) for cases I, II, and III; these curves are plotted in...
Fig. 5. It is clear that \( \kappa \) for STT only is independent of \( j_0 \) (see inset) and thus it turns to be \( \kappa_0 \) and numerically estimated to be 2.39 erg/cm\(^2\). By contrast, in the two cases including the OH effect, the \( \kappa \) value varies linearly with \( j_0 \), thereby yielding the slope \( d\kappa/dj_0 = 1.9 \times 10^{-8} \) erg/A. Consequently, the effective potential energy accounting for the OH effect can be rewritten as \( W_{\text{tot}}(X) = W_{\text{tot}}(0) + (\kappa_0 + \kappa_{\text{OH}})X^2/2 \), where \( \kappa_{\text{OH}} \) is an additional term associated with the OH contribution. From the slopes of the \( \kappa \) versus \( j_0 \) curves shown in Fig. 5, we obtain \( \kappa_{\text{OH}} = 6.4 \times 10^{-8} \) erg/A for the given Py dot, leading to the relation of \( \kappa_{\text{OH}} = 6.14 \times 10^{-8} \) erg/A for the positive rotation sense of the OH relative to the vortex chirality.

Note added in proof: All numerical values of \( j_0 \) should be corrected by multiplying \( \pi/4 \).

25. Exponentially decreasing or steady-state orbital motions can appear under specific conditions.
26. From the present simulations, the critical current density is obtained as \( j_{\text{c}} = 6.4 \times 10^{5} \) A/cm\(^2\) for STT only, \( j_{\text{c}} = 6.8 \times 10^{5} \) A/cm\(^2\) for STT + OH(P), and 6.1 \times 10^{5} \) A/cm\(^2\) for STT + OH(AP). These deviations for the case of additional OH effect are within \( \pm 5\% \) of that for STT only.
