Purpose: To evaluate the safety and efficacy of a novel medical device to provide cooling anesthesia to the eye as local anesthesia for intravitreal injections.

Study Design: First in human, open-label study of 43 subjects assessed at three different doses: -10°C for 20 seconds (group 1), -15°C for 15 seconds (group 2), and -15°C for 20 seconds (group 3). Main outcome measures were safety and pain of injection using a numeric rating scale (NRS).

Results: Cooling anesthesia did not result in any serious ocular adverse events. One grade 1 adverse event was a vasovagal response during cooling administration which resolved immediately after cooling. Mean NRS scores at the time of injection for each group ranged from 2.5 to 4.3. There was a statistically significant difference between pain scores of the 3 groups at injection in aggregate but not in pairwise comparisons (P value = 0.047). There was a statistically significant decrease in pain from injection to 5 minutes post injection in all groups (P value = 0.00008, 0.003, 0.0005 for groups 1, 2, 3, respectively) as well as from 5 minutes to 24–48 hours (P value = 0.00001, 0.018, and 0.0545 for groups 1, 2, 3, respectively).

Conclusion: The rapid cooling anesthesia device was well tolerated for achieving local anesthesia among patients receiving intravitreal injections with no serious ocular adverse events.

Keywords: intravitreal injection, anesthesia, cooling, pain

Introduction

Intravitreal injections (IVT) have become the most common procedure performed by retina specialists with an estimated 6 million IVTs in 2016.¹ Given the high volume of IVTs performed, there has been strong interest in optimizing the patient experience as well as the clinical workflow.

A number of studies have demonstrated that patients can have significant anxiety and discomfort during IVT. Studies have observed that the step most associated with significant discomfort and anxiety was the needle penetration itself, versus the preparation or waiting.^{2,3} Current methods of anesthesia for IVTs include topical anesthetic drops, application of a cotton tip applicator soaked with lidocaine, preservative free lidocaine gel, as well as subconjunctival lidocaine injection. All of these methods have advantages and tradeoffs in terms of time of onset of anesthesia as well as patient comfort with no consensus. In the 2019 American Society of Retina Specialists (ASRS) Preferences and Trends (PAT) survey, 23% of retina

specialists used topical drops, 18% used pledgets soaked with lidocaine, 25% used lidocaine gel, and 34% used subconjunctival lidocaine injection,⁴ similar to previous published IVT anesthesia surveys.⁵

Prospective studies as well as systematic reviews comparing the efficacy between different methods of anesthesia have been mixed, with the majority suggesting there is no difference in pain scores between these methods of anesthesia.^{6–11} Factors which influence the choice of anesthesia by retina specialists include patient satisfaction, procedure workflow and efficiency, and cost. An alternative method of anesthesia that is well tolerated by patients and has a rapid onset of action may improve both the patient experience as well as clinical workflow.

Using low temperatures as a form of anesthesia for medical applications has been investigated in many settings, and is commonly used as anesthesia for injection of dermal fillers.^{12,13} Mechanisms for anesthesia using low temperature include decreased nerve conduction which inhibits the firing of pain receptors, and release of endorphins.^{13,14} Here, we define the term “cooling anesthesia” as the focal application of temperatures slightly below freezing (usually between -10 and -20 degrees Celsius) as a method of local anesthesia. This temperature is much higher than temperatures that have been shown to cause tissue damage to the eye, such as from cryotherapy.^{15–17} The initial proof of concept that low temperatures could anesthetize the eye was a case report that demonstrated that use of gloved ice applied to the conjunctiva and sclera of the eye for 2 minutes was sufficient to effectively anesthetize the eye for IVT for a patient with a lidocaine allergy.⁸ Additionally, in a randomized open label study, patients administered ice packs for 2 minutes over the eyelid prior to topical anesthesia and injection resulted in statistically significant lower pain scores compared to the control group.¹⁸ Recently, a clinical study with a prototype cooling device demonstrated that cooling anesthesia was well tolerated, had a rapid onset of action, and pain from cooling anesthesia was not significantly different than lidocaine gel as measured by a visual analog scale (VAS).¹⁹

To extend this work, a clinical grade next-generation handheld cooling device was developed. In the current manuscript, we report results from a first in human study using this cooling device to evaluate the safety and feasibility of providing local anesthesia for IVT.

Methods

Study Design

This trial was a prospective, open-label, dose-escalation clinical trial evaluating the safety of a handheld precision cooling device. The study consisted of a single visit dose-escalation study design assessing 3 ascending treatment doses of the cooling anesthesia device: 1) -10°C for 20 seconds, 2) -15°C for 15 seconds, and 3) -15°C for 20 seconds. Each study site was responsible for assessing only two of the three treatment doses, with a common dose (-10°C for 20 seconds) between the two sites.

Following consent, subjects proceeded with the intravitreal injection as per investigator discretion using the cooling device for anesthesia. 5 ± 2 minutes following injection, patient pain was assessed using the Numeric Rating scale (NRS) (Figure 1). Two questions were asked using the following standardized script

On a scale of 0–10 with 10 being the worse pain you have ever felt in your life, how was your pain 1) during the injection and 2) now, 5 minutes after injection.

A slit lamp biomicroscopy exam and indirect ophthalmoscopy was performed 30 ± 15 minutes after the injection to assess for adverse effects. A follow-up phone call 24–48 hours after the injection was then used to assess pain.

Institutional Review Board (IRB) approval was obtained for each study site prior to subject enrollment (Western Institutional Review Board (WIRB) Puyallup, WA). Written informed consent was obtained from all subjects prior to performing any study procedures. The study was performed in accordance with the tenets of the Declaration of Helsinki and Good Clinical Practice

Figure 1 Numerical Rating Scale used in the COOL-I study.

guidelines. COOL-1 was registered prospectively at ClinicalTrials.gov (NCT03732287).

Cooling Device

The device used was a reusable handheld battery-powered device with an attached disposable tip (diameter of 7mm), with the following regulatory certificates: electrical safety test (IEC60601-1), EMC test (IEC60601-1-2), biocompatibility test (ISO10993), cleaning process validation (ISO11737-1), packaging process validation (ISO11607-1), and validation of sterilization (ISO11137-2006, ASTM F1980-2016, ASTM F88, ASTM F1140, ASTM F1929-15, ASTM F2096-11) (Figure 2). The device provides the cooling temperature to the eye surface at a precision of $\pm 2^{\circ}\text{C}$. The accuracy and precision of the device cooling temperature were found to remain unaffected after one thousand uses at an ambient temperature ranging from 10°C and 27°C .

Study Participants

Subjects 18 years of age or older were eligible if they were undergoing unilateral IVT using an FDA-approved anti-VEGF pharmaceutical as part of their standard of care management, and had previously received a minimum of 3 prior IVT. Subjects were excluded from the study if they had severe dry eye and conjunctival, episcleral or scleral pathologies.

Injection Procedure

The injection procedure was performed by first instilling one drop of 0.5% proparacaine into the eye to allow for application of the device to the ocular surface. A lid speculum or manual opening of the lids was then used to expose the eye for injection. Betadine was then applied

to the site of injection. The cooling device was then applied between 10 and 20 seconds adjacent to the corneal limbus. A visible, transient scleral indentation was present after cooling administrations. Another drop of betadine was applied and the injection was performed within 30 seconds of the anesthesia within the scleral indentation, indicating the area which was anesthetized. A 30 gauge $\frac{1}{2}$ inch needle was used for all injections.

Outcome Measures

The primary outcome measure of this study was safety as assessed by adverse effects during cooling anesthesia and slit lamp examination and dilated indirect ophthalmoscopy after the injection procedure. Adverse events were graded using the Common Terminology Criteria for Adverse Events (CTCAE).²⁰ Secondary endpoints included pain during the intravitreal injection as assessed by the participant's response to a 11-point visual NRS after the procedure (Figure 1). This is a previously validated outcome measure used to evaluate pain of intravitreal injections in similar studies (Clinical trials.gov, NCT01926977). Additional pain outcome measures that were analyzed in this study included the participant's pain NRS score of the intravitreal injection at timepoints of 5 minutes and 24–48 hours after the procedure, as assessed by verbal assessment. Time for the total injection procedure was also recorded.

Statistical Analysis

Descriptive statistics of pain score outcomes were calculated with means and standard deviations. One-way ANOVA analysis with Tukey's multiple comparisons was used to compare pain outcomes between dose groups. Results of quantitative analysis were plotted and include 95%

confidence interval error bars. For all analyses, P values ≤ 0.05 were considered statistically significant. Analyses were conducted in Prism 8 (GraphPad Software, San Diego, CA). As this was a first in human study designed for safety, no formal sample size calculation was performed.

Results

Study Participants

A total of 43 subjects were enrolled into the study. Demographics are presented in Table 1. Patients had received a mean of 22.6 (range 3 to 44) prior IVTs prior to COOL-1 enrollment, and had received subconjunctival injection of lidocaine as their anesthetic for all previous injections.

Safety

Cooling anesthesia at all doses was well tolerated. Of the 43 cooling anesthesia applications performed during this study, there was one occurrence of an unexpected Grade 1 adverse event thought to be related to the cooling event. While receiving the -10°C for 20 seconds cooling application, this subject experienced a vasovagal response. The

event was transient and completely resolved without treatment. There were no other serious adverse events, or serious ocular adverse events (Table 2). Of note, there was no evidence of conjunctival thinning, scleral thinning, or corneal damage after cooling administration.

NRS Pain Scores

The mean NRS pain score \pm SD scores at the time of injection are found in Table 3. There were no statistically significant pairwise group differences in pain scores at injection (Figure 3). However, there was a statistically significant difference between the 3 group measures of pain at injection in aggregate (One way ANOVA, P value = 0.047). There were no statistically significant differences in pain scores between groups 5 minutes post injection or 24–48 hours post injection (One way ANOVA P value = 0.676 for 5 min post injection, and 0.32 for pain 24–48 hours) (Figure 3). NRS pain scores were also compared over time for each group. There was a statistically significant decrease in the pain score at the time of injection to the pain score 5 minutes post injection in all groups (paired t test, P value = 0.00008, 0.003, 0.0005 for -10°C for 20 seconds, -15°C for 15 seconds, and -15°C for 20 seconds respectively) (Figure 4, Table 3). There was a statistically significant difference between pain scores 5 minutes post injection and pain scores 24–48 hours post injection in the 10°C for 20 seconds and -15°C for 15 seconds, but not in the -15°C for 20 seconds (paired t test; P value = 0.00001, 0.018, and 0.0545 for -10°C for 20 seconds, -15°C for 15 seconds, and -15°C for 20 seconds respectively) (Figure 4).

Time of Injection

The time to perform injection from the start of the injection procedure (adding drop of proparacaine to finishing the injection) was recorded for all injections. Mean time for the injection procedure was 2.05 minutes, with a standard deviation of 1.75 minutes.

Discussion

In this first in human clinical study, the safety of a clinical grade precision cooling device was evaluated across multiple treatment regimens. Cooling anesthesia during IVT offers potential advantages over current methods of anesthesia, including rapid onset of action and a nonpharmacologic approach. The current study consisted of subjects who had received multiple prior IVTs, all with subconjunctival lidocaine as their previous anesthetic.

Multiple studies on cryotherapy on human eyes suggest that the cooling temperatures used in the current study do not cause damage to the eye. Rabbit studies on corneal endothelial viability were assessed following application of cryotherapy to the cornea at various temperatures for 20 seconds. No endothelial cell loss was detected at -10 °C with largely reversible cell loss observed at -20 °C.²¹ Another study by Maumenee et al²² applied a cryotip at -78 °C to a rabbit cornea for 5 seconds (6 mm treatment spot) and reported cellular damage within the first 5 days that completely resolved at days 10 and 12. Based on this literature, we incorporated cooling temperatures (maximum of -20°C)

that have not caused irreversible damage to eye tissue in preclinical animal models.²¹

The results of the current study indicate that the device was well tolerated with no serious adverse events or serious ocular adverse events. No signs of conjunctival scarring or thinning with this single administration were observed. One grade 1 adverse event occurred among 43 cooling administrations, a transient vasovagal response that resolved without intervention. Various physiological responses, such as the oculocardiac reflex which can result in bradycardia have been observed with intravitreal injections which potentially could lead to a vasovagal response.²³ We believe that this adverse event is related to the cooling anesthesia, as this response began during cooling administration. Further work will need to evaluate the incidence of this event; we have not observed a vasovagal response in more than 200 additional cooling applications using the same device in a different clinical trial.²⁴

The NRS scale was used as patients with poor visual acuity from some of these diseases may not have sufficient visual acuity to accurately use the VAS score. These pain

scores are in a similar range of pain scores reported from other prospective studies evaluating anesthetic agents during IVTs.¹⁰ While this study was not powered to detect differences in pain scores between different cooling regimens, we did not observe any statistically significant difference of pain scores at the time of injection in pairwise comparisons between the three groups. It should also be noted that the sensitivity of this pain scale to detect small changes in pain perception is unknown. Of note, all three cooling regimens resulted in a rapid decrease in pain scores at 5 minutes and pain scores were minimal 24–48 hours after injection, suggesting that cooling anesthesia did not cause lasting pain.

A single drop of 0.5% proparacaine was applied before cooling anesthesia application. While proparacaine rapidly anesthetizes the ocular surface, the cooling device simultaneously cools the eye surface including the sclera within 10 seconds, providing rapid and sufficient anesthetic effect for IVT. Thus, one potential benefit of the cooling device is that cooling anesthesia can be applied immediately after instillation of the topical anesthetic, allowing one to perform IVT immediately after examination, which may have benefits for patients and physicians. We found that the average time required for IVT from start to finish was approximately 2 minutes, which may be considerably faster than other times for IVT using other types of anesthesia, particularly for lidocaine gel and subconjunctival lidocaine, which generally requires 5–15 minutes to achieve maximal clinical

effect. These characteristics may affect the patient experience of injection, which may be an important consideration. Future studies are indicated to quantify the effect on patient experience, and to determine if patients may prefer this type of anesthesia compared to other methods. It should be noted, however, that this short time (eg, 2 minutes) could lead to confounding contribution of proparacaine to the NRS pain scores, as topical anesthetic can also anesthetize the eye surface for intravitreal injection.

There are multiple limitations to the present study. The study was not powered to determine differences between treatment regimens. The sample size used in this study is representative of a first in human clinical trial. Future studies will need to address potential confounders such as the study population (patient diagnosis and concomitant medications), pain due to betadine application, and previous anesthetic used. Furthermore, this study was unblinded and did not use a control group. A randomized, masked trial will need to be performed to assess the efficacy of cooling anesthesia compared to other methods of anesthesia for IVTs.

In summary, the cooling anesthesia used in the current study was safe and well tolerated for patients receiving IVT as standard of care management for their retinal disease. The specific properties of cooling anesthesia, particularly its rapid onset of action, may offer unique benefits for the patient experience. Further investigation is needed to understand the long-term effects of repeated cooling

anesthesia use, and its effectiveness compared to current standard of care anesthetics.

Data Sharing Statement

The authors do not plan to share deidentified patient-level data given this data is for an investigational device that has not been approved by any regulatory authorities.
